

Source Seeking in Unknown Environments with Convex Obstacles

Bruno A. Angélico¹, Luiz F. O. Chamon², Santiago Paternain³, Alejandro Ribeiro², and George J. Pappas²

Abstract—Navigation tasks often cannot be defined in terms of a target, either because global position information is unavailable or unreliable or because target location is not explicitly known *a priori*. This task is then often defined indirectly as a source seeking problem in which the autonomous agent navigates so as to minimize the convex potential induced by a source while avoiding obstacles. This work addresses this problem when only scalar measurements of the potential are available, i.e., without gradient information. To do so, it constructs an artificial potential over which an exact gradient dynamics would generate a collision-free trajectory to the target in a world with convex obstacles. Then, leveraging extremum seeking control loops, it minimizes this artificial potential to navigate smoothly to the source location. We prove that the proposed solution not only finds the source, but does so while avoiding any obstacle. Numerical results with velocity-actuated particles, simulations with an omni-directional robot in ROS+Gazebo, and a robot-in-the-loop experiment are used to illustrate the performance of this approach.

I. INTRODUCTION

Navigation tasks are often defined by specifying a target position that the autonomous agent must attain [1], [2]. This, however, requires access to global information that is scarce in many applications. For instance, when navigating underwater or in-door, global position information is either not available, due to the lack of GPS signal, or unreliable, due to the high cost of obtaining long-term accurate inertial measurements. What is more, the target location need not be known explicitly *a priori*, e.g., when locating the source of an oil spill [3] or radio source localization [4]. A common way solution for these scenarios is to define the robot’s task indirectly as a source seeking problem.

Source seeking can be abstracted as the problem of minimizing (maximizing) a convex (concave) potential induced by the source. Though the potential is unknown, its values and more importantly its gradient can be estimated from sensor measurements. A gradient controller can then be used to drive the robot to the potential’s minimum (maximum) as long as it navigates an open convex space, i.e., an environment without obstacles [5], [6]. This solution is appealing not only because it does not require prior explicit knowledge of the goal, but because of its simplicity and the fact that they require only local information.

³ Dept. of Electrical, Computer and Systems Engineering, Rensselaer Polytechnic Institute, USA (paters@rpi.edu)

Still, if this method is to be useful in real-world applications, two issues must be addressed: (i) how to obtain good enough gradient estimates from local, scalar measurements and (ii) how to navigate cluttered environments. The main approaches used to tackle issue (i) involve variations of the classical Robbins-Monro algorithm, such as random directions for stochastic approximation (RDSA) [7], [8], [9] or sinusoidal extremum seeking control (ESC) [5], [6], [10], [11]. Albeit effective, the stochastic nature of the former may lead to non-smooth trajectories as the robot takes both random steps to sample values of the potential and steps in the direction of the estimated gradient. Although sinusoidal ESC does not suffer from this issue, the fact remains that neither methods are guaranteed to work in the presence of obstacles.

Artificial potentials can be used to navigate cluttered environments using gradient dynamics [issue (ii)]. The idea is to combine the attractive potential defining the agent’s goal with repulsive potentials representing the obstacles. Yet, careful combination is required to avoid creating spurious local minima that would prevent the robot to complete the original task. Nevertheless, by following the gradient of Koditschek-Rimon potentials or navigation functions, an agent is guaranteed to navigate to the minimum of a strongly convex potential while avoiding strongly convex, non-intersecting obstacles [12], [13], [14], [15]. In [16], an ESC scheme was used for the first time in a navigation application with NF.

This paper tackles the practical problem of source seeking from scalar measurements in a cluttered environment. To do so, we use local measurements from the objective potential and (partial) knowledge of obstacles to construct an artificial potential (Section III-A) that the agent navigates using an ESC loop (Section III-B). Note that neither the target nor the environment needs to be known *a priori*: the artificial potential is evaluated online from sensor measurements. The main contributions of this work include showing that under mild conditions on the geometry of the free space and the source’s potential, this autonomous system is guaranteed to navigate to the source while avoiding collisions (Section IV) without *a priori* knowledge of the environment. The scheme is validated using realistic simulation in a ROS+Gazebo environment as well as an experiment with an omni-directional robot navigating around spherical obstacles (Section V).

II. PROBLEM FORMULATION

As we mentioned in the introduction, we pose the problem of source seeking in a cluttered environment as that of minimizing an unknown scalar potential through a trajectory

defined in a non-convex space. Explicitly, let $\mathcal{X} \subset \mathbb{R}^2$ be a non-empty, compact, convex set delineating an environment that contains non-intersecting (possibly unknown) obstacles represented by the open convex sets $\mathcal{O}_i \subset \mathcal{X}$ with non-empty interior and smooth boundaries $\partial\mathcal{O}_i$. The *free space*, i.e., the space of points that the agent can occupy, is then defined as

$$\mathcal{F} = \mathcal{X} \setminus \bigcup_i \mathcal{O}_i. \quad (1)$$

Our goal is to reach a source located at $\mathbf{p}^* \in \text{int}(\mathcal{F})$ (unknown) that induces a strongly convex potential $f_0 : \mathcal{X} \rightarrow \mathbb{R}_+$ such that $\mathbf{p}^* = \text{argmin}_{\mathbf{p} \in \mathcal{X}} f_0(\mathbf{p})$, where $\mathbf{p} = (x, y)^T$. Observe that many physical phenomena, such as those involving spherical wave propagation or $1/r^2$ decay, induce strongly convex potentials. We wish to do so using only scalar measurements of the potential f_0 and while remaining in the free space \mathcal{F} at all times. Formally, our goal is to generate a trajectory $\mathbf{p}(t)$ for the agent such that $\mathbf{p}(t) \in \mathcal{F}$, for all $t \in [0, \infty)$, $\lim_{t \rightarrow \infty} \mathbf{p}(t) = \mathbf{p}^*$, and $\dot{\mathbf{p}}(t)$ is a function only of $f_0(\mathbf{p}(\tau))$ for $\tau \leq t$, i.e., without gradient measurements.

Notice that the space \mathcal{F} in which the robot will navigate is punctured and therefore non-convex. Hence, even if the gradient of f_0 were known, simple gradient dynamics is not guaranteed to stay within \mathcal{F} . This problem can be circumvented by constructing an artificial potential such as the Koditschek-Rimon navigation function from local measurements [12], [15]. However, the question remains of whether gradient estimate errors would lead to collisions. Though this issue was addressed for stochastic estimates in [17], stochastic approximation methods may lead to highly discontinuous trajectories.

To address these issues, we start by describing the two building blocks of our solution: navigation functions and sinusoidal ESC (Section III). We then introduce our solution and prove that, if the source potential is the strongly convex and of the obstacles are convex and non-intersecting, any particle following this policy will approach the source while remaining in the free space (Section IV). Finally, we illustrate the performance of our method using an omni-directional robot navigating a space with spherical obstacles (Section V).

III. TECHNICAL BACKGROUND

In this section, we briefly introduce the two building blocks we use to address the problem of source seeking in cluttered environments: navigation functions and sinusoidal ESC. More detailed discussions of these topics can be found, e.g., in [15] and [18] respectively.

A. Navigation Functions

Navigation functions are artificial potentials that enable collision-free navigation of spaces with obstacles. Explicitly, a map $\nu : \mathcal{F} \rightarrow [0, 1]$ is said to be a *navigation function* towards \mathbf{p}^* in \mathcal{F} if (i) $\nu \in \mathcal{C}^2$ (twice continuously differentiable), (ii) ν is polar at \mathbf{p}^* , (iii) ν is Morse, and

(iv) $\partial\mathcal{F} = \nu^{-1}(1)$ [12]. This map is called a navigation function because the dynamical system

$$\dot{\mathbf{p}} = -\nabla\nu(\mathbf{p}) \quad (2)$$

navigates the free space \mathcal{F} until it reaches \mathbf{p}^* [19].

In this work, we use the Rimon-Koditschek navigation function φ from [12]. This potential is constructed by describing each obstacle \mathcal{O}_i as the null sublevel set of a convex function $\beta_i : \mathcal{X} \rightarrow \mathbb{R}$. Explicitly, $\mathcal{O}_i = \{\mathbf{p} \in \mathcal{X} \mid \beta_i(\mathbf{p}) < 0\}$. Such a function always exists since every convex set is the sublevel set of a convex function [20]. Then, for $\beta(\mathbf{p}) = \prod_i \beta_i(\mathbf{p})$, the Rimon-Koditschek potential is defined as

$$\varphi(\mathbf{p}) \triangleq \frac{f_0(\mathbf{p})}{(f_0^k(\mathbf{p}) + \beta(\mathbf{p}))^{1/k}}, \quad (3)$$

where $k > 0$ is a fixed order parameter and f_0 is the potential induced by the source. Note that if the obstacles (β_i) are known, then $\varphi(\mathbf{p})$ can be evaluated by measuring the potential $f_0(\mathbf{p})$. If they are not, φ can be built online as the agent encounters the obstacles. In this case, if the obstacles are ellipsoids, the functions β_i can be estimated by measuring their curvatures [15].

It has been established that for sufficiently curved worlds, the artificial potential (3) is a navigation function for large enough k [21], [15]. What is more, even when the gradient in (2) is replaced by a stochastic approximation, the agent is guaranteed to navigate the free space to \mathbf{p}^* under mild conditions [17]. However, in order to deal with practical robotic applications, we wish to obtain smoother trajectories than the ones produced by stochastic gradient approximations. To do so, we rely on extremum seeking dynamics.

B. Sinusoidal Extremum Seeking Control

The idea of ESC emerged in the context of gradient-free optimization [22], having since spread to applications in model-free control, adaptive control, and source seeking [23], [24], [25], [5], [6], [10], [11], [26]. The basic ESC loop is shown in Fig. 1. Intuitively, ESC uses a small periodic perturbation $\alpha \sin(\omega t)$ to explore the landscape of the function f around θ . Assuming f is a smooth convex function, this perturbation creates a periodic response in y that is in phase with respect to $\sin(\omega t)$ if $\theta > \theta^*$ or out of phase if $\theta < \theta^*$, for $\theta^* = \text{argmin}_\theta f(\theta)$. The feedback loop then corrects θ until it stabilizes at θ^* . Another way to understand ESC is by noticing that the high-pass filter (HPF) and the demodulator are effectively estimating the gradient of f [18]. Naturally, the HPF cut-off frequency must be lower than that of the sinusoidal perturbation ($h < \omega$).

The loop in Fig. 1 is guaranteed to converge to the minimum θ^* for reasonable choices of parameters and under mild conditions on f [27]. Since, these results have been extended to vector-valued parameters and loops including nonlinear plants dynamic [18]. It is not however straightforward that using ESC to approximate the navigation function dynamics in (2) will lead to a safe trajectory. Indeed, though this combination will eventually reach the source location \mathbf{p}^* ,

Fig. 1. Sinusoidal extremum seeking controller for static map and minimization purposes.

it need not do so through a trajectory that remains in the free space. To guarantee this is the case, we need to show that the ESC loop provides a sufficiently accurate estimate of the navigation function gradient for all t . In the next section, we extend the ESC loop in Fig. 1 to the two-dimensional case and describe how the navigation function in (3) can be evaluated using local measurements. We then prove that the ESC loop follows the potential gradient closely enough, showing that this approach is able to navigate a cluttered environment without collision to reach the source of interest.

IV. SOURCE SEEKING WITH SCALAR MEASUREMENTS

The proposed solution is described here. To do so, we consider a velocity-actuated point mass as in [5]. A straightforward extension to omni-directional robots is explored in the experiments of Section V. Though the presence of more involved dynamics has been considered in the context of navigation functions [28] and ESC [18], we defer this issue for future work.

A diagram of the hybrid navigation function/ESC solution is presented in Fig. 2(a). A similar approach was considered in [16], though omitting the HPF in the ESC. While this allows for a more direct analysis of the system dynamics, it requires that the source potential be unbiased ($f_0(\mathbf{p}^*) = 0$), which limits its application. In the current setting, the agent senses the source by measuring its potential at the current location $\mathbf{p} = (x, y)^T$. It then evaluates the navigation function φ in (3) by incorporating partial knowledge of the obstacles, i.e., using $\hat{\beta}(\mathbf{p}) = \prod_{i \in \mathcal{K}} \beta_i(\mathbf{p})$ where \mathcal{K} is the set of obstacles that the agent has encountered so far. This value is then fed into a two-dimensional version of the ESC loop from Fig. 1, constructed as in [5] by using orthogonal perturbations, namely $\sin(\omega t)$ and $\cos(\omega t)$. Finally, the gradient estimate from the ESC loop is feedback to the agent actuators.

The ESC loop in Fig. 2 is guaranteed to converge to a small neighborhood around \mathbf{p}^* . Indeed, [5] showed that the source estimation error converges to a $\mathcal{O}(\alpha^2 + 1/\omega^2)$ -neighborhood of zero for reasonable choices of the gains C_x, C_y . Since φ is polar, this implies that $\lim_{t \rightarrow \infty} \mathbf{p}(t) \in \mathcal{N}^*$, a small neighborhood of \mathbf{p}^* . This, however, does not guarantee that $\mathbf{p}(t) \in \mathcal{F}$ for all $t \geq 0$, i.e., that the agent does not collide with obstacles. To show this is the case, we must demonstrate that ESC not only converges to the minimum of φ , but does so by closely

Fig. 2. Source seeking with scalar measurement in cluttered environment for velocity-actuated particle: (a) implementation diagram; (b) rearranged version using in the proof of Theorem 1.

following its gradient. In other words, demonstrate that ESC in fact approximates the dynamics in (2). The following theorem characterizes the trajectory $\mathbf{p}(t)$ and shows that under mild conditions, the agent approaches the source while avoid obstacles.

Theorem 1: Consider the dynamical system in Fig. 2a and assume that $C_x = C_y = C \ll h \ll \omega$ and $\alpha \ll 1$, i.e., that the loop gains are small compared to the HPF cut-off and perturbation frequencies and that the amplitude of the perturbation is small. Then, there exists a safety guard $\sigma = \mathcal{O}(\alpha C/\omega)$ such that if the agent considers virtual obstacles inflated by σ , it will navigate collision-free to a neighborhood of \mathbf{p}^* .

Proof: Due to space constraints, we provide a sketch of the proof below. Detailed derivations can be found in [29].

Start by noticing that the block diagram in Fig. 2a can be rearranged as in Fig. 2b using the linearity of the integrators. Then, assuming $C_x = C_y = C$, the dynamical system in Fig. 2b is described by the coupled differential equations

$$\dot{\hat{\mathbf{p}}} = -C\mathbf{z}(\omega t)(\bar{\varphi}(\hat{\mathbf{p}}, \omega t) - \eta(t)) \quad (4a)$$

$$\dot{\eta}(t) = h[\bar{\varphi}(\hat{\mathbf{p}}, \omega t) - \eta(t)], \quad (4b)$$

where $\hat{\mathbf{p}} = (\hat{x}, \hat{y})^T$ denotes the particle position, $\mathbf{z}(u) = [\sin(u) \quad -\cos(u)]^T$ is the modulation vector, and $\bar{\varphi}(\hat{\mathbf{p}}, u) = \varphi(\hat{x} + \alpha \sin(u), \hat{y} - \alpha \cos(u))$. Note that $\mathbf{p}(t) = \hat{\mathbf{p}}(t) + \alpha \mathbf{z}(\omega t)$. To obtain an approximate solution of (4), we start by using the classical multi-timescale approximation [30]. Since $C \ll h$, there is an initial layer $t = \mathcal{O}(C/h)$ during which $\hat{\mathbf{p}}$ is nearly constant and close to its initial value, while $\eta(t)$ converges exponentially fast to the quasi-steady-

state $\eta_0(\hat{\mathbf{p}}(0))$ for

$$\eta_0(\hat{\mathbf{p}}) = h e^{-ht} \int e^{ht} \dot{\bar{\varphi}}(\hat{\mathbf{p}}, \omega t) dt. \quad (5)$$

Then, for $t = \mathcal{O}(1)$, the value of η is close to its slow manifold, i.e., $\eta(t) = \eta_0(\hat{\mathbf{p}}(t)) + \mathcal{O}(C/h)$, and $\hat{\mathbf{p}}(t)$ satisfies (4a) with $\eta(t) = \eta_0(\hat{\mathbf{p}}(t))$.

Having decoupled η from $\hat{\mathbf{p}}$, we can now apply the averaging method to (4a). To do so, normalize the timescale taking $\tau = \omega t$ and use the fact that $\varphi \in \mathcal{C}^2$ to obtain a Taylor expansion of $\bar{\varphi}$ around $\hat{\mathbf{p}}$. Then, observe that the resulting expression is of the form $\dot{\hat{\mathbf{p}}} = \varepsilon g(\hat{\mathbf{p}}, \tau)$, where g is 2π -periodic in τ and $\varepsilon = \frac{\alpha C}{\omega}$. Hence, $\hat{\mathbf{p}}(\tau) = \hat{\mathbf{p}}_{av}(\tau) + \mathcal{O}(\varepsilon)$, where $\dot{\hat{\mathbf{p}}}_{av} = \varepsilon g_{av}(\hat{\mathbf{p}}_{av})$ for $g_{av}(\mathbf{v}) = \frac{1}{2\pi} \int_0^{2\pi} g(\mathbf{v}, \tau) d\tau$ [31, Thm. 10.4]. Explicitly,

$$\dot{\hat{\mathbf{p}}}_{av} = -\frac{\alpha\omega C}{2(h^2 + \omega^2)} \begin{bmatrix} 1 & \frac{h}{\omega} \\ -\frac{h}{\omega} & 1 \end{bmatrix} \nabla\varphi(\hat{\mathbf{p}}_{av}). \quad (6)$$

Though (6) does not follow the gradient dynamics (2), it can be shown to also avoid obstacles by showing that whenever $\beta(\hat{\mathbf{p}}_{av}) = 0$, i.e., $\hat{\mathbf{p}}_{av}$ is on the boundary of an obstacle, $\dot{\beta}(\hat{\mathbf{p}}_{av}) > 0$ and the trajectory returns to the free space. Since the actual trajectory \mathbf{p} closely follows $\hat{\mathbf{p}}_{av}$, as long as there is a safety guard of $\mathcal{O}(\alpha C/\omega)$ around each obstacle, the trajectory $\hat{\mathbf{p}}$ is collision-free and converges to a neighborhood of \mathbf{p}^* according to [5, Thm. 1]. ■

V. PERFORMANCE RESULTS

Three different scenarios were considered. In the first one, a Matlab simulation with a simple velocity-actuated particle model was performed. In the second case, a more realistic simulation with a commercial Quadruple Mecanum Robot was carried out using ROS+Gazebo. Lastly, an experiment considering real dynamics with a robot-in-the-loop was considered. In all cases, the obstacles were inflated approximately by the radius of the robot, and the source potential was modeled as:

$$J = f_0(\mathbf{p}) = q_x(x - x_s)^2 + q_y(y - y_s)^2 \quad (7)$$

A. Velocity-actuated Particle

The parameters of the ESC were chosen such that $\omega = 40$ rad/s, $\alpha = 0.07$, $C_x = C_y = -10$ and $h = 20$. The world consists in a circled environment with radius 3 m and five round obstacles with radius 0,25 m at the points $(-1.0, 0.0)$, $(-0.25, 1.2)$, $(1.0, 0.7)$, $(1.0, -1.0)$, $(-0.5, -1.0)$, respectively. For the source potential, it was considered $q_x = q_y = 1.0$, and for the navigation function, it was set $k = 6$. The starting point of the robot was set to $(0.2, 2.5)$.

We first present the simulation considering that the source is static and located at position $(0, 0)$, as shown in Fig. 3. For the sake of presentation, the level sets of the exact NF and its true gradient are also plotted. As can be seen, the source was found by the robot and the resulting path was very close to the true gradient.

Fig. 4 considers the case of a slow time varying source. The source starts static and, after for 10 s, it follows the dashed red line path with speed $v_l = 0.2$ [m/s]. The source

Fig. 3. Static source with unknown position. The level sets of the NF are plotted considering that the source position is known. The particle's trajectory estimated by the extremum seeking is in black color and the true gradient of the NF is in magenta color; the "x" marker is the starting point $(0, 2.5)$ and the red "o" is the source location $(0, 0)$.

stops at position $(-0.47, 0.38)$ and keeps there until the end of the simulation. The particle finds the source while it is moving and tracks it up to the final position.

Fig. 4. Moving source with $v_l = 0.2$ [m/s]. The robot's trajectory is in black color, the "x" marker is the starting point and the red "o" stands for the initial and final source location. The robot finds the source and tracks it up to the final position.

B. Quadruple Mecanum Robot

A more realistic simulation was also carried out considering the Mecanum robot MPO-500, from Neobotix, which is a commercial robot with four mecanum wheel, as depicted in Fig. 5. It is ROS compatible and has a Gazebo model. The main features of this robot are presented in Table I.

Fig. 5. Robot Neobotix, model MPO-500 [source: neobotix-robots.com].

TABLE I
PARAMETERS OF THE NEOBOTIX MECANUM ROBOT MPO-500.

Parameter	value
Payload Default	50 [kg]
Dimensions ($L \times W \times H$)	$986 \times 662 \times 409$ [mm]
Max. linear speeds (v_x and v_y)	0.8 [m/s]
Uptime	up to 7 h or up to 3 km
Sensors	1 or 2 2D laser scanner

Simulations were performed in ROS+Gazebo using Rospy. ESC parameters were chosen such that $\omega = 2.5\pi$ rad/s, $\alpha = 0.15$, $C_x = C_y = -200$ and $h = \omega/2$. These values violate the gain assumption in Theorem 1. The world consists of a circular environment with radius 7 m and five round obstacles, $(4.5, 6.0, 0.35)$, $(6.5, 3.0, 0.7)$, $(6.0, 8.5, 0.7)$, $(10.5, 7.5, 0.35)$ and $(11.0, 4.0, 0.35)$, here denoted in the form (x, y, r) , r being the radius. The starting point of the robot is at $(2.0, 6.0)$.

Three simulations were considered. In the first one, all the obstacles are previously known, while in the second one, three out of five are known. In these two cases, it was considered $q_x = q_y = 1.0$, and for the NF, it was set $k = 5$.

In the third result it is assumed that none of the obstacles is known *a priori* and k starts equal to zero. The initial potential (with $k = 0$) is set as $0.1f_0(\mathbf{p})/(0.1f_0(\mathbf{p}) + \beta_0)$. When a new obstacle is detected, k is incremented by one.

The ESC algorithm was discretized with a sampling frequency equal to $\omega_s = 10\omega$. The maximum linear speed was limited to 0.8 m/s. A rosbag file was generated during the simulations to record the ROS topics.

Figs. 6 and 7 present the results when all the obstacles are known. It is possible to see that the trajectory of the robot follows the true gradient of the navigation function and the robot finds the source without hitting any obstacles.

Fig. 6. Gazebo simulation considering the Neobotix MPO-500. It is assumed that all the obstacles are previously known. The source location is at the mid-field.

Next results consider that the obstacles $(6.5, 3.0, 0.7)$, $(10.5, 7.5, 0.35)$ and $(11.0, 4.0, 0.35)$ are known *a priori*. Fig. 8 shows the robot's trail in the Gazebo world, while Fig. 9 presents the trajectory of the robot on the level sets of the NF, in three different moments: two right before the navigation function being updated, and the final trajectory. When a new obstacle is found, the NF is updated. The robot successfully finds the source, avoiding all the obstacles.

Next and more interesting result considers a completely unknown environment. Initially, $k = 0$, but it increases by one when a new obstacle is found. Fig. 10 shows the trail of

Fig. 7. Plot of the robot's trajectory. The level sets of the NF are plotted considering that the source position is known.

Fig. 8. Gazebo simulation considering the Neobotix MPO-500. Three out of five obstacles are known.

Fig. 9. Trajectory of the robot on the level sets of the NF in three different moments, right before the updates of the NF and the final trajectory. The axes limits are the same of Fig. 7.

the robot in the Gazebo, while Fig. 11 presents the trajectory on the level sets of the NF. Again, the robot was able to find the source and avoid every obstacle in the way.

Even not satisfying the assumption $C_x, C_y \ll h$ in Theorem 1, in all case, the robot was able to find the source and avoid all obstacles. We set high values for the loop gains because of the potential normalization imposed by the NF. Moreover, it is worth mentioning that the maximum speed of the robot was limited to 0.8 [m/s].

Fig. 10. Gazebo simulation with Neobotix MPO-500, assuming that none obstacles are known *a priori*.

Fig. 11. Trajectory of the robot on the level sets of the NF in four moments, being three right before the updates of the NF, and the final trajectory. Obstacles are unknown *a priori*. Axes limits are the same of Fig. 7.

C. Triple Omniwheel Robot

The parameters of the ESC were chosen such that $\omega = 2.5\pi$ rad/s, $\alpha = 0.15$, $C_x = C_y = -20$ and $h = \omega/2$. The world consists in a circled environment with radius 2.2 m and five round obstacles with radius 0.13 m at the points $(1.0, 0.0)$, $(1.5, 1.0)$, $(1.5, -1.0)$, $(2.5, 0.75)$, $(2.5, -0.75)$, respectively. The experiment was performed with the real robot present in Figure 12, but the measurements of the source potential was artificially generated, according to Eq. (7), using odometry. As in the last case of the previous subsection, it is assumed that the obstacle are unknown. However, since the robot has no lidar yet, there is a table with all the obstacles positions and it is assumed that when the robot gets close to an obstacle, its position and curvature are instantaneously detected and, thus, the NF is updated. That is the reason why we called this experiment as real dynamics with robot-in-the-loop. The ESC algorithm was discretized with a sampling frequency equal to $\omega_s = 10\omega$. The maximum x and y speeds were limited to 0.6 m/s.

This robot was built for this experiment using a FRDM-K64F micro controller board from NXP. Its main parameters are shown in Table II. A velocity controller is implemented for each wheel and the set-points are determined from v_x

Fig. 12. Triple Omniwheel Robot.

TABLE II
PARAMETERS OF THE TRIPLE OMNIWHEEL ROBOT.

Parameter	value
Wheels' radius (R)	0.03 [m]
Distance from center to the wheels (L)	0.15 [m]
Robot's max. linear speeds (v_x and v_y)	0.6 [m]
Robot's angular speed (Ω_R)	0.0 [rad/s]

and v_y (from the ESC algorithm) considering the inverse kinematics. Practical result is presented in Figure 13. Notice that though it violates the assumptions of Theorem 1, the robot could still reach the source collision-free.

Fig. 13. Results with robot in the loop. In a) it is presented the robot's trajectory (in black) considering the whole scenario, while b) shows the same trajectory with the obstacles detected by the robot and the level sets of final estimated navigation function with its true gradient (in magenta).

VI. CONCLUSIONS

This paper addressed the problem of source seeking with scalar measurements in spaces cluttered with convex obstacles. To do so, the autonomous agent builds a navigation function online based on a local measurement of the source potential and its (partial) knowledge of obstacles. A sinusoidal ESC loop was then used to minimize this artificial

potential so as to smoothly navigate to the source location. Theoretical results guarantee that, under mild conditions, the robot attains its goal while avoiding collisions. Experiments with velocity-actuated particles and omni-directional robots corroborated the efficiency of the method, even in situations where no knowledge of the environment is available. Future works include testing this method with real potential measurements and extending it to 3D navigation for quadrotors or unmanned underwater vehicles.
